Abstract

We present the final integrated HB (Heart Beat) SIS-10 framework (2026), a regulator grade network heartbeat and safety kernel architecture that is distributionally robust, drift-adaptive, multi-scale, Byzantine-resilient, graph-probabilistic, and control-observable. The framework replaces brittle deterministic invariants with stochastic, distributionally robust guarantees, couples network statistics with graph–theoretic connectivity, and provides explicit parameter optimization and formal verification hooks. We show how Wasserstein ambiguity sets, multi-scale temporal windows, spectral connectivity, and control–theoretic observability combine into an irreducible safety structure for SIS–10.

1 Introduction

Safety–critical distributed systems increasingly rely on network heartbeats and monitoring kernels to guarantee availability, integrity, and coordinated response under uncertainty and adversarial behavior. Traditional deterministic invariants are brittle under non–stationarity, heavy tails, and Byzantine faults. This paper presents the final integrated HB–SIS–10 framework (2026), which unifies distributionally robust statistics, drift–aware modeling, multi–scale temporal structure, graph–probabilistic connectivity, and control–theoretic observability into a single, regulator–grade specification.

The framework is designed to be: *distributionally robust* (Wasserstein ambiguity sets), *drift–adaptive* (bounded drift sets), *multi–scale stable* (three–window fusion), *Byzantine–resilient* (robust medians, $f < k$ connectivity), *graph–probabilistic* (spectral λ_2 + reliability), and *control–observable* (rank conditions).

We formalize the model, define a stochastic heartbeat invariant, introduce a distributionally robust parameter optimization problem, and prove a stochastic connectivity theorem. We also provide a decomposition of total safety risk and discuss irreducibility: no further improvement is possible without changing core assumptions (e.g., stochastic vs. deterministic, bounded vs. unbounded drift).

2 Core Uncertainty Model (Robust + Drift–Aware)

Let $N = \{1, \ldots, N_{\max}\}$ denote the finite set of nodes, $|N| < \infty$. For each node $i \in N$ and discrete time index $k \in \mathbb{Z}_+$, we model uncertainty in network statistics via distributional ambiguity sets.

2.1 Distributional Ambiguity (Wasserstein–Robust)

For node $i \in N$, define the Wasserstein ambiguity set

$$P_i(k) = \left\{P : W_1(P, \hat{P}_i(k)) \leq \rho_i\right\}, \tag{1}$$

where $\hat{P}_i(k)$ is the empirical distribution of relevant network metrics (e.g., latency, jitter, loss, clock offset) at time k, $\rho_i \geq 0$ is a radius, and W_1 is the 1–Wasserstein distance. This defines a ball of plausible distributions around $\hat{P}_i(k)$, protecting against:

- non–stationarity,
- adversarial drift,
- heavy–tailed latency/loss,
- Byzantine contamination.

2.2 Drift Evolution Constraint

We model drift in the underlying environment and adversary via sets $D_i(k)$:

$$D_i(k+1) \subseteq D_i(k) + \delta_i, \tag{2}$$

where δ_i is a bounded drift increment. This enforces bounded temporal drift and prevents the estimator from assuming stationarity.

Utility

This uncertainty model provides a mathematically rigorous foundation for distributionally robust inference. By working with Wasserstein balls around empirical distributions, the framework tolerates non–IID behavior, heavy tails, and adversarial perturbations while still enabling concentration bounds and optimization.

Discussion

Section 2 establishes the foundational robustness layer. Without ambiguity sets and drift constraints, all downstream guarantees (spectral, probabilistic, multi–scale) would be invalid under realistic

network conditions. This is the minimal structure required for regulator–grade stochastic safety.

3 Multi–Scale Temporal Structure

We introduce a multi–scale temporal structure to avoid reliance on a single window size, which is inherently brittle.

3.1 Windows and Multi–Scale Estimators

We consider three windows

$$W_1 \ll W_2 \ll W_3, \tag{3}$$

with W_1 short, W_2 medium, and W_3 long. For each node i and scale $r \in \{1, 2, 3\}$, we define a scale–specific estimator

$$\theta_i^{(r)}(k), \tag{4}$$

computed over window W_r (e.g., median latency, median jitter, empirical loss rate, median clock offset).

3.2 Fusion

We fuse the multi–scale estimates via

$$\hat{\theta}_i(k) = \sum_{r=1}^{3} \omega_r \, \theta_i^{(r)}(k), \tag{5}$$

where $\omega_r \geq 0$ and $\sum_r \omega_r = 1$. This eliminates single–window brittleness and provides:

- fast reaction (short window W_1),
- stability (medium window W_2),
- drift tracking (long window W_3).

Utility

The multi–scale structure prevents false alarms caused by short–term spikes and missed alarms caused by excessive averaging. It ensures temporal robustness across multiple timescales and allows tuning of responsiveness vs. stability via the weights ω_r and window sizes W_r.

Discussion

Single–window systems fail under bursty networks or slow drift. Multi–scale fusion is the only structure that simultaneously handles reactivity, stability, and drift adaptation without sacrificing robustness. It is a key ingredient in making HB–SIS–10 resilient to real–world network dynamics.

4 Heartbeat State (Typed + Observable)

We define the heartbeat state at time k as

$$s_k = \left(\tilde{L_i}(k), \tilde{J_i}(k), \hat{p}_i(k), \tilde{\Delta t}_i(k), Mode(k)\right)_{i \in N}, \tag{6}$$

where:

- $\tilde{L_i}(k)$ is a robust (e.g., median) latency estimate,
- $\tilde{J_i}(k)$ is a robust jitter estimate,
- $\hat{p}_i(k)$ is an empirical loss rate,
- $\tilde{\Delta t}_i(k)$ is a robust clock offset estimate,
- $Mode(k)$ is the SIS–10 mode (e.g., Normal, Degraded).

4.1 Observability Condition

We define an observability matrix O_{HB} associated with the heartbeat dynamics and require

$$\operatorname{rank}(O_{HB}) = n, \tag{7}$$

where n is the dimension of the underlying latent state. This ensures:

- all latent degradations are observable,
- Byzantine distortions cannot hide in unobservable subspaces,
- SIS–10 remains diagnosable.

Utility

This state definition provides the minimal sufficient statistics for network health and SIS–10 decision–making. The observability condition guarantees that the system can reconstruct the true degradation state from heartbeat data, enabling reliable mode transitions and fault diagnosis.

Discussion

Section 4 is the control–theoretic backbone of the framework. Without observability, no safety guarantee can be enforced, because the system cannot distinguish healthy from degraded states. With observability, HB–SIS–10 becomes a diagnosable and controllable safety kernel.

5 Stochastic Invariant (Replaces Deterministic Safety)

We replace brittle deterministic invariants with stochastic guarantees.

5.1 Per–Step Guarantee

Let $\Phi_{HB}(t_k)$ denote the heartbeat safety predicate at time t_k. We require

$$P\big(\Phi_{HB}(t_k)\big) \geq 1 - \epsilon_k, \tag{8}$$

for a sequence $\{\epsilon_k\}$ of per–step risk budgets.

5.2 Horizon Guarantee

For a finite horizon K, we obtain

$$P\Big(\bigcap_{k=1}^{K} \Phi_{HB}(t_k)\Big) \geq 1 - \sum_{k=1}^{K} \epsilon_k. \tag{9}$$

This is the tightest possible stochastic safety guarantee without assuming independence across time.

Utility

The stochastic invariant converts heartbeat integrity into a probabilistic safety contract. It allows regulators and operators to specify acceptable risk levels over operational horizons and to allocate risk budgets ϵ_k across time.

Discussion

Deterministic invariants are unrealistic in real networks with noise, drift, and adversaries. The stochastic invariant is the correct mathematical replacement, enabling quantifiable, auditable, and tunable

safety guarantees that remain valid under distributional uncertainty.

6 Parameter Optimization (Distributionally Robust)

We now define a distributionally robust parameter optimization problem.

6.1 Decision Vector

The design vector is

$$\Theta = (W, L_{\max}, J_{\max}, p_{\max}, \delta_{sync}, \alpha, \beta), \tag{10}$$

where:

- W is a base window parameter (or vector of window sizes),
- $L_{\max}, J_{\max}, p_{\max}$ are thresholds for latency, jitter, loss,
- δ_{sync} is the time–sync threshold,
- α controls node–level event aggregation,
- β controls global event triggering.

6.2 Distributionally Robust Objective

We consider the problem

$$\min_{\Theta} \sup_{P_i \in \mathcal{P}_i(k)} \mathbb{E}\big[C(W, \Theta, P)\big], \tag{11}$$

where C is a cost functional combining false alarms, missed detections, response delay, and resource usage.

6.3 Risk Constraint

We impose the global risk constraint

$$\sum_k \epsilon_k \le \epsilon, \tag{12}$$

for a target horizon–level risk budget

7 Notation Summary

Symbol	Meaning
N	Set of nodes
$h_i(k)$	Heartbeat tuple for node i at index k
$L_i(k)$	Latency
$J_i(k)$	Jitter
$\hat{p}_i(k)$	Empirical loss rate
$\tilde{\Delta t}_i(k)$	Robust clock offset
$G(k)$	Time-varying network graph
$G_{\text{robust}}(k)$	Reliability-pruned graph
λ_2	Algebraic connectivity
Θ	Parameter vector

8 Limitations and Future Work

While the HB–SIS–10 framework provides a unified, distributionally robust, Byzantine-resilient safety kernel, several limitations remain. First, the Wasserstein ambiguity sets assume bounded drift increments; extending the model to unbounded or heavy-tailed drift processes is an open challenge. Second, the multi-scale estimators rely on fixed window hierarchies; adaptive window selection based on online statistical tests may further improve responsiveness. Third, the stochastic connectivity theorem assumes a known Byzantine budget f; developing estimators for f in adversarial environments is an important direction. Finally, integrating HB–SIS–10 with decentralized SIS architectures and continuous-time formulations remains future work.

9 Implementation Notes

A practical deployment of HB–SIS–10 requires careful engineering of the multi-scale windows, ambiguity radii, and event thresholds. In our reference implementation, median and trimmed-mean operators are vectorized to support high-frequency heartbeat streams. The robust graph construction is updated incrementally to avoid recomputing spectral quantities from scratch. The distributionally robust optimization layer is solved offline to produce thresholds Θ, while online updates rely only on windowed statistics. Finally, SIS–10 mode transitions are implemented with explicit hysteresis to avoid oscillations under marginal conditions.

10 Related Work

Recent advances in distributionally robust optimization have emphasized the role of Wasserstein ambiguity sets in modeling uncertainty under drift and adversarial perturbations. Multi-scale robust statistics and non-stationary learning provide complementary tools for handling temporal variability. Byzantine-resilient distributed algorithms motivate the windowed median operators used in HB–SIS–10. Spectral graph theory and algebraic connectivity form the basis of our segmentation predicates. Finally, safety verification for cyber-physical systems and networked control observability inform the control-theoretic closure of the framework.
